Hot Cognition or Cool Consideration
Testing the Effects of Motivated Reasoning on Political Decision Making

Abstract

Researchers attempting to understand how citizens process political information have advanced motivated reasoning to explain the joint role of affect and cognition. The prominence of affect suggests that all social information processing is affectively charged and prone to biases. This paper makes use of a unique dataset collected using a dynamic information board experiment to test important effects of motivated reasoning. In particular, affective biases should cause citizens to spend longer processing information incongruent with their existing affect, and such biases should also direct search for new information about candidates. Somewhat perversely, motivated reasoners may actually increase their support of a positively evaluated candidate upon learning new negatively evaluated information. Findings are reported which support all of these expectations. Additional analysis shows that these affective biases may easily lead to lower quality decision-making, leading to a direct challenge to the notion of voters as rational Bayesian updaters.

Hot Cognition or Cool Consideration

Testing the Effects of Motivated Reasoning on Political Decision Making

Much of the study of voters and elections focuses on the vote itself. Political scientists have advanced many different models to explain how preferences are turned into votes. But before a citizen can cast a vote, he or she generally must learn something about candidates and make some effort to compare the alternatives across a set of salient attributes. Two competing schools of thought have developed about the way in which evaluation proceeds. For rational theorists, voters are Bayesian updaters coolly considering new information in light of prior preferences and accurately updating those preferences by lowering evaluations upon encountering negative information and increasing evaluations when learning positive information (Gerber and Green, 1999.) Political psychologists, however, caution that the process of updating prior evaluation may be subject to a range of unconscious biases designed to support prior preferences, rather than to rationally update them. For these motivated reasoners (Kunda, 1987; 1990; Lodge and Taber, 2000) candidate evaluation may be more about reinforcing existing feelings about candidates rather than revising them in the face of new information.

The empirical support for motivated reasoning is promising, but somewhat limited to date.[1] As Gerber and Green (1999) forcibly argue in a defense of the Bayesian model, the simple laboratory experiments in which bias has been shown differ substantially from the real world of political information processing. Political campaigns are ultimately about making decisions between candidates but existing studies have not examined candidate choice. In this paper I

respond to this critique with a new dynamic process tracing experiment in which subjects actively participate in a simulated presidential election campaign, search for information about candidates, and decide which one deserves their vote. Using this design, I find significant evidence that during routine information processing both search and candidate evaluation are biased towards existing preferences, and that these biases lead to sub-optimal decision making. Voters in this study, at least, do not follow the dictates of coolly considered Bayesian updating unless specifically motivated to do so, which I suggest does not represent the way most people process information most of the time.

Candidate evaluation is much like evaluating any other person. Such evaluation routinely occurs on-line, that is, evaluation of other people is continuous and immediate upon acquisition of information (Hastie and Park, 1986; Hastie and Pennington 1989; Lichtenstein and Srull 1987.) When asked to report their evaluation, on-line processors need only retrieve the tally that maintains the current affect towards the target. Thus, on-line processing is seen to be efficient processing, in the tradition of the cognitive miser (Taylor, 1981.) Studies by Lodge and his colleagues have established on-line processing as a widely accepted view of how voters consider candidates[2] (Lodge, McGraw, and Stroh, 1989; Lodge, Steenbergen, and Brau, 1995.)

The efficiency of routine on-line processing may well come with a price. The same directional goals that motivate towards immediate evaluation of information may drive information search towards reinforcing existing affect and reaching a specific pre-selected conclusion. These motivated reasoners may discount, counter-argue, or simply ignore new information that challenges existing evaluation and affect. (Kunda, 1987, 1990; Lodge and

Taber, 2000.) Information congruent with expectations is easily assimilated, since it requires no effort to accept what one already knows is true. But incongruent information interrupts normal processing and instead engages a process where some effort must be expended to make sense of the world.[3]

Thus affect and cognition interact for the motivated reasoner engaging in the evaluation of another person. The interaction is driven by what Lodge and Taber (2000) describe as a three-part process: on-line processing, hot cognition, and the "How-do-I-feel?" heuristic. Memory for on-line processors contains not only cognitive information but also the affective on-line tally, updated immediately upon the acquisition of new information. Hot cognition (Anderson, 1981) suggests that affect is automatically activated along with the cognitive node to which it is tied.[4] Finally, the process of on-line evaluation and the structure of hot cognition result in a "How-do-I-feel?" heuristic mechanism for evaluating new information. Simply put, when new information is encountered, the affect associated with relevant existing knowledge interacts with affect towards the new information to form a virtually instantaneous assessment of the new information.[5] The result of this process can be bias towards maintaining existing affect even in the face of disconfirming information.

In order to study on-line processing and motivated reasoning, a reference point is necessary. Researchers usually contrast on-line processing with memory processing (Hastie and Park, 1986.) Memory processors withhold evaluation until the moment of decision, when the contents of memory are used to inform the choice. Research shows quite clearly that on-line processing is the default when processors have directional goals, that is, when they wish to

generate a global evaluation (Hastie and Pennington, 1989; Lichtenstein and Srull, 1987.) In order to generate memory processing, some intervention is usually required. Typically, researchers provide an accuracy motivation to interfere with on-line processing and to motivate towards memory processing (Hatie and Pennington, 1989.) The motivation towards accuracy is believed to interfere with the evaluative goals that drive on-line processing (Neuberg, 1987; Neuberg and Fiske, 1987.) Comparing accuracy motivated subjects with those processing in the default on-line manner allows researchers to highlight the role played by the interaction of cognition and affect.

Hypotheses

As voters encounter information about political candidates they develop affect towards those candidates. The affect may be positive or negative, strong or weak, but it ought to be apparent in the processing of new information as it is encountered. The clearest indication of the motivated reasoning process would be if voters encountering affectively incongruent information about candidates take longer to process that information compared to congruent information. Learning something one does not like about a favored candidate is to learn incongruent information, as is learning something positive about a disliked candidate while information with an affective valence in the same direction as existing affect is considered congruent.

When encountering incongruent information, motivated reasoners may spend time counterarguing against it, making an effort to fit it into their existing affect about the target (Lodge and Taber, 2000.) Other processes may also be engaged, including bolstering existing

affect by recalling from memory the reasons for it. In any case, these processes take time to carry out. Congruent information, however, does not require any special effort since it easily fits existing expectations. Given that motivated reasoning rests in part on on-line processing, this pattern should be particularly evident for on-line processors motivated by a directional goal, such as candidate evaluation. Memory processing and an accuracy motivation however, may be expected to counteract this process, since the effort to maintain memory and accuracy may cause processors to focus equal attention on all types of information. This leads to Hypothesis 1:

> H_1: Voters processing on-line and motivated towards directional goals will take longer to process new affectively incongruent information about a candidate for whom an affective evaluation already exists, compared to congruent information about the same candidate. Voters motivated towards accuracy goals and memory processing will not show these effects.

Motivated reasoning also has implications for information search. Lodge, Taber, and Galonsky (1999b) show a confirmation bias during information search about political issues when subjects knew the likely valence of available information. For candidate information processing a similar effect could be expected, as motivated reasoners seek to confirm their feelings towards candidates, perhaps assuming that they will a priori like what a favored candidate has to say. It is not as clear whether such a bias should be expected from memory processors motivated towards accuracy. Kunda (1990) suggests that in some circumstances

accuracy goals are not enough to overcome bias. If so, memory processors may show the same biases towards preferred candidates that are expected of on-line processors. Thus, Hypothesis 2:

> H_2: Once initial affect towards a candidate is established, voters will spend more time searching for information about preferred candidates and avoiding disliked candidates.

Lodge, Taber, and Galonsky (1999a), and Lodge and Taber (2000) report an important and counterintuitive result in that many subjects evaluating issue information report even stronger support for their pre-treatment issue positions after encountering arguments incompatible with their own position. Rather than attenuate their attitudes by incorporating the views expressed in the new incongruent information, motivated reasoners appear to discount arguments opposed to their position.[6] Once again the question is whether this finding extends to the realm of political candidates competing for the vote in a campaign. If so, attitude strengthening is the likely result, leading to Hypothesis 3:

> H_3: Voters who are on-line processors will show increased support for preferred candidates if they encounter incongruent information about those candidates. Memory processors, motivated towards accuracy, will not show a similar increase in support under the same conditions.

If voters strengthen their support for a preferred candidate even in the face of negative information about that candidate, what is the likely result in an election context? Such voters

might well be led astray by their affect, ultimately voting for a sub-optimal candidate simply because they start out liking that candidate based on early information. This suggests that the order of information search is important, and that a voter who learns positive information early about a candidate is likely to find it difficult to adjust affect and change candidates even if later information search turns up negative information. In this fashion, motivated reasoning predicts a process similar to anchoring and adjustment (Tversky and Kahneman, 1974) but one in which the anchor is far stronger than the adjustment, and the adjustment may in fact be in the wrong direction. Such process would clearly violate the requirements of Bayesian updating.

H_4: Attitude strengthening effects will lead to lower quality decisions. As a motivated reasoner encounters greater amounts of negative information about a preferred candidate and therefore strengthens the positive affect towards that candidate, a lower quality vote decision will result.

Method

Dynamic Process Tracing

Process tracing starts with the assumption that decision-making is best studied by collecting data while the decision is actually being made (Ford, Schmitt, Schectman, Hults, and Doherty, 1989; Jacoby, Jacard, Kuss, Troutman, and Mazursky, 1987.) The major research technique is the information board, which presents subjects with a static m x n matrix of information. Subjects choose among several alternatives (columns of the matrix) which differ on one or more attribute (rows.) Richard Lau and I have revised the traditional static information

board, modifying it into a dynamic, ever-changing simulation mimicking the flow of information during a political campaign (Redlawsk and Lau 1995; Lau and Redlawsk 1997; Redlawsk, 2001, Lau and Redlawsk, 2001a; Lau and Redlawsk, 2001b.) Where the static board allows subjects to have access to all available information at all times the dynamic board emulates the ebb and flow of a political campaign over time. The essential feature of the static information board -- the ability to trace the decision-making process as it happens -- is retained while information about candidates comes and goes. A real election campaign contains a "here today, gone tomorrow" quality to its information flow and so does the dynamic information board. Finally, where the standard information board makes all types of information equally accessible, from positions on arcane issues to party identification, the dynamic approach models the relative ease or difficulty of finding certain kinds of information at different times during a campaign.

Using this dynamic process tracing methodology a unique dataset has been collected incorporating observations of the information processing techniques employed by subjects as they negotiate an election campaign. Data have been collected on what subjects learn about each candidate, how long they spend processing each discrete piece of candidate information, their likes and dislikes about candidates and issues, and more, all collected unobtrusively as subjects engage in political information processing. At the end of the campaign subjects report their memories about the candidates, their global affect towards the candidates and the affective value of each memory they can recall. As a means of testing the effects of both information and affect, the dynamic information board provides the best available insight into what voters are actually doing during a campaign.

Procedure

A total of 99 subjects participated in a mock presidential primary election featuring six candidates, divided between the two parties.[7] Subjects were told that the computer would present the kind of political information which would normally be available in a primary election and that the candidates, while all invented, were designed to represent a realistic ideological spectrum for their respective political parties. Subjects were registered as either Democrat or Republican prior to the election, and could only vote for the candidates from within the chosen party though they could actually learn about all six candidates. By creating mock candidates crucial control was retained over the differences between subjects in prior knowledge of actual politicians since no subject knew anything about any of the candidates ahead of time.[8] The specific procedures followed by subjects are detailed in Figure 1.

Insert Figure 1 about here

Two manipulations crucial to this analysis were embedded in the primary election.[9] The processing manipulation was designed to randomly assign subjects into either an on-line or memory-based processing mode. Since on-line processing is the default method by which people evaluate social information (Hastie and Park 1986; Lodge, McGraw and Stroh 1989; Lodge 1995) and given that all subjects knew they would have to vote for a candidate, the existing incentive to form an evaluation and process on-line was strong. Accordingly, no specific instruction was given to create the on-line condition. Subjects in the memory-based condition

were instructed that they would be required to list everything they could remember from the campaign once the election was over, in effect, being warned that memory mattered. Memory-based subjects were also instructed that they would have to justify their vote choice to the experimenter (Lodge, 1995.) This should have had the effect of creating a memory-based accuracy motivation for this group of subjects. The memory instructions were embedded in the general instructions subjects read at the beginning of the primary election simulation.

The second crucial manipulation, the poll interruption, provides a way of assessing candidate affect prior to the end of the campaign. One-third of subjects were interrupted after one-third of the campaign had passed and asked if the election were held at that point for whom would they vote. After their preference was recorded they were returned to the campaign. A second third of the subjects were interrupted with the same poll question after two-thirds of the campaign. The final third were not interrupted by a poll and thus made their only evaluation at the end of the election.

Following completion of a political attitudes and knowledge questionnaire and an opportunity to practice with the computer, subjects experienced a twenty-minute primary election campaign presented via the dynamic information board. The flow of information in the simulation was dictated by the flow of information during “real world” presidential campaigns (Lau, 1995.) Subjects accessed this information by clicking on a statement such as "Thomas's position on Term Limits" and reading a "card" on the computer screen listing the information. In addition each candidate had two twenty-second campaign videos that appeared at various times without being chosen. At the end of the primary, subjects voted for one candidate in their party.

Subjects then took a memory test (unexpected for those in the on-line condition) in which they were instructed to list everything they could remember about each candidate. After an exercise to establish whether subjects had cast a "correct vote" (Lau and Redlawsk 1997), an extensive debriefing and cued recall procedure began. Subjects were shown the script of all information they had examined and asked to recall what they were thinking while learning each piece of information, as well as to evaluate each as to whether its contents made the subject feel good, bad, or neutral about the candidate. The time required for each subject was about 2 1/4 hours.

Defining Congruency

Congruency is defined as the relationship between existing affect for a candidate and the affect generated by the new information encountered about the same candidate. In order to operationalize information congruency, affect towards the candidates and affect towards new information must be determined. Three measures of affect towards candidates are available. First, subjects were asked to rate each of the six candidates in the Republican and Democrat primaries on a standard 101-point feeling thermometer. A candidate is defined as liked by the subject if the candidate's rating on the feeling thermometer is above the subject's mean rating for all six candidates. Conversely, the candidate is considered disliked if the rating is below the subject's mean for all candidates. Affect towards any candidate rated at the mean is considered neutral and dropped from analyses using this measure. Second, affect can be defined based on the actual vote cast at the end of the campaign, since all subjects voted for a candidate they liked. The third measure of candidate affect is found in the poll which two-thirds of subjects were

asked to answer while the campaign was underway. In this case, affect towards the candidate chosen in the poll is believed to be positive at the time the poll was administered.

Affect towards new information about the candidates was measured by using the cued recall procedure in which subjects were shown the script recording their information search. Information that subjects said made them feel good about a candidate was coded positive and that which made them feel bad was coded negative, while neutral information was dropped from this analysis.[10] Information congruency then simply crosses the two measures, so that congruent new information (in which affect for the new information matched affect for the candidate) was coded as 1 and incongruent coded as 0. The unit of analysis is the pairing of subjects and information, so that for each subject there are as many observations as there are cards of information examined for each candidate.

Results

Information Congruency and Processing Time

Cognitive research shows that incongruent information can be more difficult to incorporate into existing schemas than schema-congruent information (Fiske and Taylor, 1991.) Steenbergen and Lodge (1998) argue that affect plays the key role. Affect, connected to the activated cognitive concept, determines if new information will be readily incorporated into the existing structure or whether more detailed processing will be needed. Hypothesis 1 predicts that for on-line processors the amount of time required to process affectively incongruent information will be greater than the time required for congruent information.

Table 1 reports the results of a series of OLS regression analyses in which the mean adjusted processing time for new information is the dependent variable, and information congruency along with a number of important controls are the predictors.[11] Because subjects knew nothing about any of the candidates in the election simulation before the campaign started, they began the study with no affect towards any candidate. Therefore time for affect to develop was allowed by discarding the first two pieces of information that a subject viewed for each candidate. The analyses for on-line and memory processing subject groups are reported separately, since very different findings are anticipated for the two groups. Controls include the remaining two experimental conditions: task demands (0=2 candidates, 1=4 candidates) and poll interruption (1=early evaluation, 2=middle evaluation, 3=late evaluation), measures of political sophistication and education, and measures of reading ability and the number of words per information card.[12] These covariates, all of which are constants within subjects, also serve the role of "dummy variables" to control for between-subjects effects created by the use of subject-candidate pairings for observations.[13]

Insert Table 1 about here

The first two columns of Table 1 report the analysis across all available subject-candidate observations. In this initial analysis no significant effects for information congruency are evident for either on-line or memory processors. The primary predictors of processing time are the number of words in each information card and the subject's reading ability. While the minimal

effects for information congruency might seem somewhat troubling, in some ways it should not be surprising. Subjects faced six candidates overall: two or four in their party and four or two in the other party. Any analysis of all candidates includes some candidates for whom affect has probably developed (those within the party) and some for whom little or no affect has developed (out party candidates; ignored candidates.) A better test of the hypothesis is to look only at candidates towards whom we are certain some affective feeling has developed.

The third and fourth columns of Table 1 show the effects of information congruency on processing examining only those candidates subjects voted for at the end of the campaign. For subjects in the on-line condition, the findings are clearly in line with the expectations of motivated reasoning. Incongruent information slows down processing, so that subjects who read information challenging their existing affect towards a candidate took significantly longer to process that information. As expected, the information congruency effect, however, does not exist for subjects in the memory processing condition. As Kunda (1987) suggests, the accuracy goal (memory processing) appears to attenuate the affective bias that is found in subjects with an evaluative goal (on-line processing.)

A potential conceptual problem arises with the analyses in the first four columns of Table 1. While affect towards the candidates is determined either by the feeling thermometer evaluations provided by subjects after the election (columns 1 and 2), or by the actual vote (columns 3 and 4), both measures were collected after the campaign and neither allows us to say with certainty that subjects held the indicated affect from beginning to end. In fact, it is very likely that at least some subjects changed their affect towards the candidates as the campaign

progressed.[14] While the results appear to support using these measures, the analysis would be better served by a measure of affect captured during the campaign. Fortunately, for two-thirds of subjects such a measure is available in the form of the poll interruption experimental manipulation that provides a measure of candidate evaluation collected while the campaign was underway.

The analyses in the last two columns of Table 1 takes into account only the information these subjects viewed after the poll was taken. All information encountered before the poll is discarded in this analysis. Subjects in the on-line condition show effects for information incongruence which are, if anything, even stronger, as would be expected if Hypothesis 1 is supported. Memory processors show very different effects. While not statistically significant, there appears a tendency for accuracy motivated subjects to focus on congruent information, spending less time on incongruent items. Overall, these findings provide clear support for the hypothesis that incongruent information about candidates slows down information processing for on-line processors, as would be expected if they are motivated reasoners.

Congruency and Information Search

Hypothesis 2 predicts that affect will influence information processing by directing information search. Table 2 reports an analysis of information search patterns. Subjects in the on-line processing condition show evidence of being guided by like/dislike for candidates in selecting information. Since there were six candidates in every primary election, purely random search would have resulted, on average, in each candidate receiving one-sixth (.167) of all

information accesses. Using this as the standard, we see that candidates who were liked by on-line voters accounted for about 21% of all information card accesses, while disliked candidates accounted for only 12%. The candidate ultimately chosen by the voter received over 25% of all information accesses. All of these information search rates are significantly different from purely random search. Memory processors were just as guided by their affect also focusing their information search on liked candidates, while exhibiting far less interest in learning about disliked candidates. This appears to support Kunda's (1990) assertion that the accuracy goal does not necessarily resolve the search and memory bias generated by affect. Overall, the results provide generally strong support for Hypotheses 2.

Insert Table 2 about here

Information Congruency and Decision-Making

I now turn to the question of whether the greater processing time and biased search processes lead to any real consequences. Hypothesis 3 predicts that motivated reasoners who encounter incongruent information about preferred candidates will exhibit stronger support for those candidates rather than reducing their support as should be expected in the face of negative information. Voters motivated towards accuracy should not show this effect. An ANOVA model was used to examine the effects of information congruency on the ratings subjects gave to the candidate chosen in the poll. Because this candidate is by definition a liked candidate, incongruent information will always be negatively evaluated information. The processing manipulation and information congruency were entered into the ANOVA in a full-factorial

design along with subject political sophistication and an indicator of whether the candidate was vote for at the end of the election as controls. As shown in Table 3, strong effects are found for the processing condition and the interaction between processing and information congruency. This interaction is what would be expected if on-line processors differ from memory processors. That they differ is not surprising, given that motivated reasoning assumes on-line processing.

The nature of the interaction becomes clear in the marginals reported in Table 3. On-line processors show exactly the attitude strengthening effects predicted by the Lodge studies, while memory processors do not. In fact, memory processors show a normatively correct pattern -- as they encounter negative information about a preferred candidate, they lower their evaluation of that candidate. On-line processors, however, increase the rating of their chosen candidate when they encounter negative information about the candidate chosen in the poll, thus supporting the expectations of Hypothesis 3. Figure 2 provides a graphical presentation for the ANOVA results, including the control variables.

Insert Table 3 and Figure 2 about here

Given the evidence that attitude updating does not occur in a normatively correct manner for motivated reasoners, it is important to see whether this leads to consequences for the actual vote choice. Hypothesis 4 predicts that voters who show attitude strengthening effects will be less likely to make a high quality decision. This follows logically from the evidence that such voters apparently ignore information that runs counter to their existing affect, rather than

adjusting their beliefs to be in line with the new information. Failure to make an accurate adjustment in attitude seems very likely to lead to sub-optimal decision-making. Ditto, et al. (1998) argue that "although people may direct attention toward preference-inconsistent information in the hope of uncovering alternative explanations for it, the effortful processing that is the by-product of that hope can lead people towards non-preferred as well as preferred conclusions" (p. 61). Information processors may be led astray by making extra effort to counteract the incongruency in information that does not support pre-defined affect. Lodge and Taber (2000) suggest that information processors counterargue against positions they do not like, and in so doing they strengthen their existing attitude rather than using the new information to update and perhaps attenuate previous beliefs. If the same process occurs when voters are learning about candidates it would suggest that those who encounter more negative information about a candidate they like would be more likely to remain with that candidate rather than switching to another, even when there might be a better candidate in the race. The result would be a lower quality decision.

In order to test Hypothesis 4 a definition of decision quality in candidate selection is needed. Lau and Redlawsk (1997) show that decision quality can be measured by allowing the voter to self-determine whether he or she would change their vote after having the chance to view all available information about the candidates in the choice set. This "fully informed" decision quality measure allows me to establish the difference between a vote cast on the basis of the information actually viewed during the campaign, and the vote which would have been cast if the voter had the time and resources to view all information about all candidates in their choice

set. Subjects in the present study were given the opportunity to change their vote to another candidate after the election was over and after spending as long as they liked reviewing all available information about all the candidates. During this process the experimenter emphasized the importance of an accurate decision and assured subjects that changing their vote was reasonable and normal. Thus all subjects were given an accuracy motivation at this point. Those who declined to change their vote were coded as casting a "correct" vote (about 75% of subjects) while those who were willing to change were coded for an "incorrect" vote.

Across all subjects in the on-line condition, a mean of 7.9% of all information encountered about the chosen candidate was reported to be incongruent, with a range from 0 to 50%. Since chosen candidates were also liked candidates, incongruent information in this context is limited to affectively negative information. Subjects who voted incorrectly, and thus evidenced lower decision quality, encountered on average 14.2% incongruent information for the candidate they selected, while those casting correct votes, and thus making a higher quality decision, reported only 5.9% incongruent information on average. The difference between these groups is significant, $t=2.521$, $p<.05$.

However, decision quality is affected by a number of factors, including maintenance of the on-line evaluation counter (Lodge, McGraw, and Stroh, 1989), the difficulty of the task environment, and the amount of accurate memory voters hold about the candidates (Redlawsk, 2001.) Thus, in order to test the role of information congruency we must start first with a model of decision quality that takes into account these factors. Such a model is reported in Redlawsk (2001) and a somewhat simplified version is taken as the starting point for this analysis as

reported in Table 4. The dependent variable is correct voting with a correct vote coded 1 and an incorrect 0. Decision quality is directly affected by the difficulty of the task, with subjects facing four candidates performing worse than those facing two candidates. In addition, subjects who spend a longer time making the decision do a better job, while those who report unconstrained political attitudes do worse. Finally, subjects who report more accurate memories for their preferred candidate also show high quality decision making, whether in the on-line or memory processing conditions. This base model correctly classifies nearly 84% of subjects.[15]

The question for the present analysis is about the nature of the information itself, that is, whether or not the congruency of new information as it relates to pre-existing affect adds anything to this basic model of decision quality. The results show that in fact information congruency significantly improves the base model. Importantly, none of the original significant predictors changes either sign or significance. Clearly the affective nature of the information viewed plays a part independent of the importance of any other factor in predicting decision quality. The main effects for incongruency show that for subjects in the on-line processing condition, encountering more incongruent (i.e. negative) information about the chosen candidate leads to a lower quality decision. This provides clear support for the motivated reasoning hypothesis that the effort to overcome disliked information about liked candidates can lead voters to discount important negative cues about a candidate they prefer. However, the incongruency by processing interaction term indicates that subjects in the memory processing condition, whose goal was accuracy rather than evaluation, showed a significant tendency to do a better job as more incongruent information was encountered. Memory processors, therefore, do

seem to take into account new information in a more accurate way than do on-line processors. These effects were independent of both task demand and political sophistication. The new model is significantly improved over the original (X^2_{diff}=14.28, 4df, p<.01) and a proportional reduction in error of .237 is shown. Hypothesis 4 is supported for on-line processors only as would be expected by motivated reasoning.

Discussion

While simulations have their limitations as analogues of "real-world" campaigns, the process that subjects followed in this study broadly resembles the processes needed to evaluate candidates: learning about the candidates, developing affect towards them, and expressing that affect by casting a vote. Because this campaign simulation proceeds over time and because subjects have no knowledge of or affect towards candidates before starting the campaign, crucial control is maintained over the information used to generate affect and the complete information search process is recorded.

The findings provide the first direct support for motivated reasoning in an environment mimicking the processes of a political campaign. Incongruent information requires significantly greater processing time for subjects in the on-line experimental condition. Further, information search was specifically focused on liked candidates, while ignoring those who were disliked. While this seems like an obvious and logical process for voters to follow, ignoring initially

disliked candidates means failing to consider completely the full choice set. The bias towards looking at liked candidates suggests that the order in which information is searched is critical. If a voter has several dimensions of interest but eliminates a candidate from consideration based on only a subset that generated negative affect early in the campaign, she ignores the possibility that an initially disliked candidate might be her best choice on many unconsidered dimensions.[15]

Most importantly, the biases generated by affect appear to have real consequences. On-line processors who encountered greater incongruency during information search showed attitude strengthening and degradation in decision quality. It appears that when incongruent information is encountered, the automatic assimilation and update process is interrupted, as greater attention is paid to the new incongruent information. During this time voters may be actively counterarguing the information, developing reasons why it is wrong or should otherwise be ignored in an attempt to explain it away (Lodge & Taber, 2000.) Or voters might bolster existing affect by searching memory for congruent information about the candidate, in a kind of balancing effort akin to that suggested by Heider's (1958) balance theory. In any case, while this study does not directly test these possibilities, it is easy to see how failing to adjust affect in accord with new incongruent information could lead to lower quality decisions as the value of the new information is discounted. The investment in candidate affect arising from learning even a small amount of information appears to create an anchor from which voters have a hard time moving in the normatively correct direction.

Yet accuracy-motivated subjects seemed to readily overcome this effect, even while still showing search biases, so that in encountering incongruent information they correctly updated

their prior affect. Memory processors do not show the longer processing times for incongruent information evident in on-line processing. And memory processors made better decisions when encountering this information; they appear to have incorporated it and adjusted their preferences accordingly, so that in the end they were more likely to vote correctly. Yet they still show the same search bias as on-line processors, preferring to search for information about liked candidates over disliked. Apparently the accuracy motivation is not enough to overcome the preference for liked candidates during information search. This preference may lead memory processors astray just as readily as on-line processors (after all, not all memory processors cast a "correct" vote.) But memory processors clearly attenuate the effects of this bias by their ability to modify their prior affect when encountering negative information about these liked candidates.

These findings provide a direct challenge to the notion of candidate evaluation as a Bayesian updating process where voters readily modify their prior expectations based on the value of new information. While Gerber and Green (1999) argue that a "Bayesian public ... is not incapable of being persuaded by new information" the results of this study leave questions about how that persuasion might work. The clear findings of attitude strengthening among on-line processors along with the evidence of lower quality decision making in the face of affectively incongruent information seems evidence that whatever process is operating, it cannot be readily squared with rational Bayesian updating.

A caveat is in order. While motivated reasoning speaks to the difficulty of assimilating incongruent information, and this difficulty is supported in the study presented here, at least some of the reason for slower processing might be the negative valence generally carried by the

incongruent information. Because this study focuses primarily on candidates subjects liked, the incongruent information they encountered was necessarily information they disliked. Studies have shown some differential effects for negative affect compared to positive, especially in the realm of person evaluation. Fiske (1980) finds that more weight is given to unusual and negative cues in evaluating personality, concluding that negative cues are considered more informative than positive ones. Pratto and John (1991) concur, showing that negative stimuli grab attention and are weighted more heavily in evaluation. There appears to be a clear asymmetrical effect between positive and negative events (Taylor, 1991.) While unable to say for certain whether the cause is the simple incongruence of new information, or its negativity the findings in this study do point clearly to important implications for information that does not match with affective expectations.

The normative implications of this line of research are important. Political scientists who prefer voters as affect-free calculators who coolly consider candidates and make even-handed evaluations if simply given enough information miss a critical piece of the puzzle. Affect counts. We can no more process political information without being aware of how it makes us feel than we can make reasoned candidate choices with no information at all. Thus we can not really hope to avoid every biases affect brings. At best, by understanding the nature of these biases we can devise ways to correct for them. Yet it is extremely difficult to understand, let alone measure, the processes inside our heads. The experimental methods used in this study can offer hope to those who aim to achieve this goal. Despite the challenges we face in order to open the black box of human information processing, the findings in this study remind us that we cannot ignore affect.

Notes

[*]Portions of the research reported in this paper were supported by a grant from the National Science Foundation, SBR-9411162. Thanks are due to those who helped in the data collection effort, Elizabeth Felter, Paul Babbit, Jill Locke, and Rachelle Brooks, and to Christa Hubby for research assistance. I also appreciate the helpful comments of Richard Lau, Marco Steenbergen, Chuck Taber, and Gary Segura on earlier drafts. Earlier versions of this paper were presented at the Annual Meeting of the International Society of Political Psychology, July 1-4, 2000 and the Annual Meeting of the Midwest Political Science Association, April 19-22, 2001. A version of this paper won the Roberta Sigel Award for Best Paper by a Junior Scholar at the Annual Meeting of the International Society of Political Psychology, July 14-18, 2001.

[1] Lodge and colleagues provide the best initial evidence of motivated reasoning in politics. A series of experiments show motivated reasoning biases operating in many phases of the political issue processing. They find that affect is intricately tied to cognition (Lodge and Taber, 2000), information processing is biased towards support for prior positions (Lodge, Taber, and Galonsky, 1999a) and information search often proceeds in order to confirm prior expectations (Lodge, Taber, and Galonsky, 1999b.) Steenbergen (2001) finds a conservatism bias operates in maintaining preferences for existing affect. None of these studies examine the role of motivated reasoning in candidate evaluation in a campaign environment.

[2] But see Zaller (1992) for some strong skepticism about the role of on-line processing. Redlawsk (2001) suggests that candidate evaluation, while proceeding on-line generally, benefits

from accurate memory processing to enhance the quality of the evaluation and decision process.

[3] Person-perception research regularly reports that trait congruency determines the ease with which traits are processed. Congruent trait pairs (pairs of traits where both traits are descriptively or evaluatively viewed as similar) generate more easily imagined personalities than do incongruent pairs while incongruent traits take longer to assimilate than do congruent traits (Casselden and Hampson, 1990.) Davies (1997) reports that favorable traits are considered more accurate statements of personality than unfavorable traits, and generate more evidence confirming their accuracy. Ditto, Scepansky, Munro, Apanovitch, and Lockhart (1998) show that information opposed to existing preferences (that is, affectively incongruent) requires more effortful processing than does congruent information.

[4] Fazio (1995) argues that the likelihood of an attitude becoming accessible upon the activation of the cognitive node is conditioned upon the strength of the association between the node and affect. Only strong associations result in automatic attitude accessibility. There is some disagreement over this claim (see Bargh, Chaiken, Govender, and Pratto, 1992.) Motivated reasoning appears to assume that attitude accessibility is all but automatic for candidates and issues of importance to voters.

[5] Some might suggest that motivated reasoning is simply a new approach to the old ideas represented by dissonance theories. While cognitive dissonance (Festinger, 1957) and balance theories (Heider, 1958) focus on the need to keep attitudes/behaviors in congruence, ascribing this need to a psychological drive, they do not directly address how affect and cognition interact. Motivated reasoning, especially in the specification of the "How-do-I-feel" heuristic, attempts a

more complete conception of the causes of biased processing, specifying under what conditions (on-line evaluation), by with what structure (hot cognition) and through what mechanism (the How-do-I-feel heuristic) bias is likely to occur. The by-product of this process may well be a tendency towards cognitive consistency.

[6] Ansolabehere and Iyengar (1995) report a similar finding in their study of negative advertising.

[7] A total of 102 subjects were recruited from central New Jersey in the fall of 1994. Of these, three could not complete the study due to fatigue or inability to operate the computer. No specific attempt was made to be representative of voters in New Jersey. Two-thirds of subjects were female and the average age was 49, ranging from 18 to 82. Twenty-five percent had household incomes over $75,000 per year, while 13% were under $25,000. Ninety-three percent were white. Partisanship was distributed as 57% Democrat, 7% independent, and 36% Republican. Subjects were recruited primarily through organizations invited to provide participants in return for a donation of $20 per participating member. These organizations included a YMCA, a senior citizen's center, a day care center, and other community organizations. Recruiting was done by the organization itself using parameters provided by the researchers.

[8] Subjects did not even know the names or parties of the candidates until the election began. The names became available immediately, as part of the information board label, e.g. "Thomas's Position on the Middle East." Party was not known until the party item was actually accessed.

[9] A third manipulation was included in the experiment and is used as a control in the analysis reported in this paper. The task demand manipulation varied the number of in-party candidates during the primary election. One half of subjects faced four candidates in their party's primary (and two in the other party), while the remaining subjects faced only two candidates in their party (and four in the other party.)

[10] Some concern is warranted for the ability of subjects to accurately recall affect. In order to minimize this problem, subjects had an opportunity to express a "don't remember" position when asked about their recall of information. Approximately 17% of items viewed were not recalled by subjects and dropped from this analysis. There is evidence in the literature that affect can be recalled reasonably accurately (Thomas and Diender, 1990.) A direct test of recall accuracy is possible using a very limited subset of items in this study. For nine of the issues, subjects were queried before the simulation on their own positions using a standard 7-point scale. Because candidates were invented and their issue positions known with certainty a comparison can be made between candidate position and subject position on this small subset of issues. This analysis shows a mean of 67% agreement across all subjects and issues between self reports of like/dislike and a constructed like/dislike measure based on subject-candidate agreement, with a range of 56% for taxes to 83% for the environment. (Other issues include crime, military intervention, abortion, affirmative action, health policy, homeless, and welfare.) These nine issues represent only about 10% of all items examined during the simulation and direct measures of others are not available.

[11] The adjusted processing time measure was calculated using the time required to read an

information card beginning when a subject clicked to access a piece of information and ending when the subject clicked on a button to return to main screen. The raw measure thus contains both actual reading time and the physical time required to move the computer mouse and click on the button. To adjust for this, the raw reading time measure was regressed within subjects on the number of words in the candidate information card. The resulting constant represents the mean time required for each subject to read a card with zero words, thus approximating the time needed to handle the task of accessing the DONE button. For each subject this constant was subtracted from the raw reading time for each piece of information accessed.

[12] Political sophistication is an index of political behavior, political interest, and political knowledge, all collected as part of a pre-experiment questionnaire. Reading ability is measured by the amount of time subjects took to read the provided instructions, as recorded by the computer.

[13] OLS regression analysis assumes no autocorrelation of residuals. Because this analysis includes multiple observations of individual subjects as they chose pieces of information, some concern about a lack of independent observations might exist. The individual difference variables, in addition to being theoretically important, control for this since they carry a constant value within subjects. An examination of the Durbin-Watson Statistic (Durbin and Watson, 1950) indicates that all regressions reported in Table 1 do not show signs of autocorrelation and thus can be considered based on independent observations.

[14] For example, 18 out of 64 subjects (28%) chose to vote for a candidate at the end of the election who was different from the candidate they preferred in a poll taken during the campaign.

[15] See Redlawsk (2001) for a comprehensive description of each of the variables in the model. In general, the on-line tally measure summarizes affect developed for candidates during the campaign. It is the additive sum of all information encountered about the candidate judged closest to the subject. The memory measure is the count of accurate memories reported for that candidate. Political sophistication is measured using a battery of political knowledge, behavior, and interest questions. Decision time is calculated as the time required to choose a candidate during the voting process. Issue constraint is a measure of how consistent subjects were in their political attitudes as reported on the questionnaire.

[16] Allison and Zelikow (1999) make a similar point about information search, as does Dawes (1988.)

Figure 1
Outline of Experimental Procedure

1. Political Attitudes Questionnaire

Subjects asked questions to measure political preferences; political interest, participation, knowledge, and media usage; importance of different types of political information for 1992 vote choice; background/demographic information (*about 30-40 minutes*).

2. Mock Primary Election Campaign

a. Practice session using the mouse to access information about 1988 Presidential election (*about 8 minutes*).
b. Explicit instructions and 1996 campaign scenario; random assignment to different experimental conditions (hidden from subjects) (*about 5 minutes*).
c. Primary election campaign involving 6 candidates (*about 22 minutes*).
d. Vote in party's primary election; evaluate all six candidates; manipulation check on difficulty of choice (*about 3 minutes*).

3. Memory Task

Subjects asked to remember as much as they can about all six primary election candidates. Task was unexpected for on-line processing condition, and expected for memory-processing condition (*about 10 minutes*).

4. Correct Voting Determination

Subjects presented with complete information about two candidates from primary (the one they voted for, and the candidate closest to the subject on the issues, of the remaining candidates in that same party) and asked to decide which they would have voted for if they had obtained all of this information when they actually had to make their choice during the primary election (*about 10-15 minutes*).

5. Detailed Protocol Analysis

Subjects completed detailed guided protocol analysis where they explained why they had selected the items they chose to examine during the primary (*about 15 Minutes*).

6. Debriefing

Subjects' general impressions of experiment gathered; any remaining questions answered; etc. (*about 5 minutes).*
